Paper XL

The Planck-to-Cosmos Scaling Framework:

Structure of the 15,027 Identity, the Surface Tension Form $\lambda = 2\sigma A_P/L^3$,

and Three Corrections to the Blueprint

What Holds, What Needs Fixing, and What Comes Next

Dervis Kadunic | Independent Researcher

Companion to Papers I–XXXIX | arXiv/Zenodo March 2026

ABSTRACT

The MSDS Council's GTP module proposed a 'Planck-to-Cosmos Scaling Law' for Paper XL, connecting the 15,027 identity from Paper XXXIX to Planck-scale surface tension through a dimensional gear ratio. This paper runs every number, confirms four structural elements, and corrects three specific claims before they enter the permanent record. What holds: the surface tension form $\lambda = 2\sigma A_P/L^3$ is the correct structure; the micro-to-macro narrative is physically compelling; the identity $A_P/(\eta \times v^2) = 15{,}027 = 15 \times 1001.8$ reveals the topological factor 15 (Paper XXXIII) embedded in the consistency check. What is corrected: $L = l_P \times \sqrt{v^2}$ gives a sub-Planck length (0.013 l_P), not proton scale; Planck surface tension σ_P plugged directly into $\lambda = 2\sigma A_P/L^3$ exceeds the cosmological vacuum energy density by 187 orders of magnitude; and the claimed expression $15{,}000 \approx 2\pi/\alpha \times f$ has no clean f. The open problem — deriving the factor 1002 in 15,027 = 15 × 1002 — is identified as the target for Paper XLI.

I. The Blueprint — What Was Proposed

GTP's Paper XL blueprint proposed a structural anchor for the 15,027 identity: a dimensionless 'gear ratio' bridging Planck-scale springs to cosmological-scale vacuum stiffness. The narrative is compelling — the smallest possible object sets the spring rate for the largest possible structure. The structure of the proposal is right. Three specific numerical claims are not.

II. What the Numbers Show

Claim 1 — Cell size $L = l_P \times \sqrt{v^2}$:

$$L = l_P \times \sqrt{(v^2)} = 1.616\times10^{-35} \times \sqrt{(0.00017)} = 1.616\times10^{-35} \times 0.013 = 2.1\times10^{-37}\ \text{m}$$

(result: sub-Planck, not proton scale)

Correction 1 — L is sub-Planck, not proton-scale:

$\sqrt{(0.00017)} = 0.013$. So $L = 0.013 \times l_P = 2.1\times10^{-37}$ m.

Proton radius = 8.41×10^{-15} m. These differ by 22 orders of magnitude.

The second formula $L = \sqrt{(15000\eta/A_P)} \times l_P$ gives 1.24×10^{33} m — still 19 orders below proton.

Neither formula gives proton scale. The 'proton radius match' is not confirmed.

$v^2 = 0.00017\ AU^2$ is an orbital-scale quantity, not a sub-nuclear one.

Claim 2 — λ from Planck surface tension:

$$\sigma_{Planck} = E_P / l_P^2 = 1.96e+09 / (1.62e-35)^2 = 7.49e+78\ J/m^2$$

(Planck surface tension — dimensionally correct)

Correction 2 — Planck σ gives cosmological constant problem:

$\lambda = 2\sigma_P \times A_P / L^3$. With Planck σ and $L \sim$ few $\times\ l_P$,

λ comes out $\sim10^{1}$■■ J/m^3.

Observed cosmological vacuum energy density ≈ 10■^{1}■ J/m^3.

Ratio = 10^{1}■■■^{1}■ = 10^{1}■■ — the cosmological constant problem in full.

Planck-scale σ cannot directly yield cosmological λ without a 120-order suppression mechanism.

This is not a MSDS-specific failure — it is the famous CC problem.

Paper XL acknowledges this and leaves σ as the open anchor.

Claim 3 — 15,000 $\approx 2\pi/\alpha \times f$:

$$2\pi/\alpha = 2\pi \times 137.036 = 861.02$$

($2\pi/\alpha$ has no clean path to 15,027)

Correction 3 — No clean expression for 15,000 in terms of α:

$2\pi/\alpha = 861.0$. To reach 15,027 requires $f = 17.45$.

No known physical constant or simple combination equals this f.

The $1/\alpha^2 = 18{,}779$ is closest (25% off) but has no MSDS motivation.

The honest position: 15,027 has not been expressed as a product

of known constants. It is a consistency identity, not a derived formula.

III. What IS Structurally Sound

The surface tension form:

$$\lambda = 2\sigma A_P / L^3$$

(correct form — A_P is the geometric weight, σ is the energy scale)

This is the right structure. A_P = 2.3451 appears as a direct linear multiplier of the surface tension — exactly as GTP proposed. The stiffness scales with how densely the Schwarz P surface is packed into the cell. The problem is not the form — it is anchoring σ to a physical scale that avoids the cosmological constant problem. The candidate: σ must be set by the dark energy scale Λ_DE, not the Planck scale.

$$\sigma_MSDS = \rho_\Lambda^{(1/2)} \times (\blacksquare c)^{(3/2)} = \text{dark energy surface tension}$$

(σ anchored to DE scale — not Planck scale)

The 15,027 structure:

$$A_P / (\eta \times v^2) = 15026.9 = 15 \times 1001.8$$

(15 is topological — Paper XXXIII; 1002 is the open problem)

KEY STRUCTURAL FINDING:

15,027 = 15 × 1001.8

The factor 15 = b■ + d² is the Schwarz P topological invariant from Paper XXXIII.

It reappears here in the Planck-to-cosmos scaling identity.

The factor 1002 is not yet derived — this is the target for Paper XLI.

If 1002 has a clean derivation, the full micro-to-macro bridge is closed.

IV. The Micro-to-Macro Narrative — Correct Structure

GTP's narrative is physically correct in structure, even if some specific numbers need revision. The picture:

- **The vacuum is a lattice:** The Schwarz P geometry (Paper XXVII) tiles space with the highest-symmetry cubic minimal surface. Every unit cell has area A_P = 2.3451.
- **The surface tension stores energy:** Each unit cell acts like a stretched membrane with surface tension σ. This is the microscopic origin of $\lambda = 2\sigma A_P/L^3$.
- **The 'gear ratio' is real:** The ratio $A_P/(\eta \times v^2)$ = 15,027 is dimensionless and connects three independently derived quantities. Something is selecting this specific ratio — and the factor 15 appearing in it suggests it is topologically enforced.
- **The cosmological constant problem is not solved:** Planck-scale σ does not directly give cosmological λ. The suppression mechanism is the outstanding gap — it requires σ to be anchored to the DE scale, not the Planck scale.

V. Complete Status Table

Quantity	Value	Source	Status
A_P	2.3451	Schwarz P topology (XXVII)	Derived
η	0.918	Horndeski EoM (XX)	Derived
v^2	0.00017	Solar system fit (I-XII)	Observed
A_P/(η×v^2)	15,027	Consistency identity (XXXIX)	Consistent
15,027 = 15 × 1002	—	15 from topology; 1002 unknown	Partial
γ = η×3H■	6.06e-18 s■¹	Hubble friction (XXXIX)	Derived
m_* = H■/v^2	8.52e-30 eV	Stiffness mode (XXXIX)	Derived
ζ = 0.0002	Underdamped	Damping ratio (XXXIX)	Derived
σ in λ=2σA_P/L^3	Open	DE scale candidate	Open
Cell size L	Not proton-scale	Sub-Planck if L=l_P√v^2	Corrected
15,000 = 2π/α×f	f not clean	No known expression	Corrected

Table 1: Complete status of Paper XL quantities.

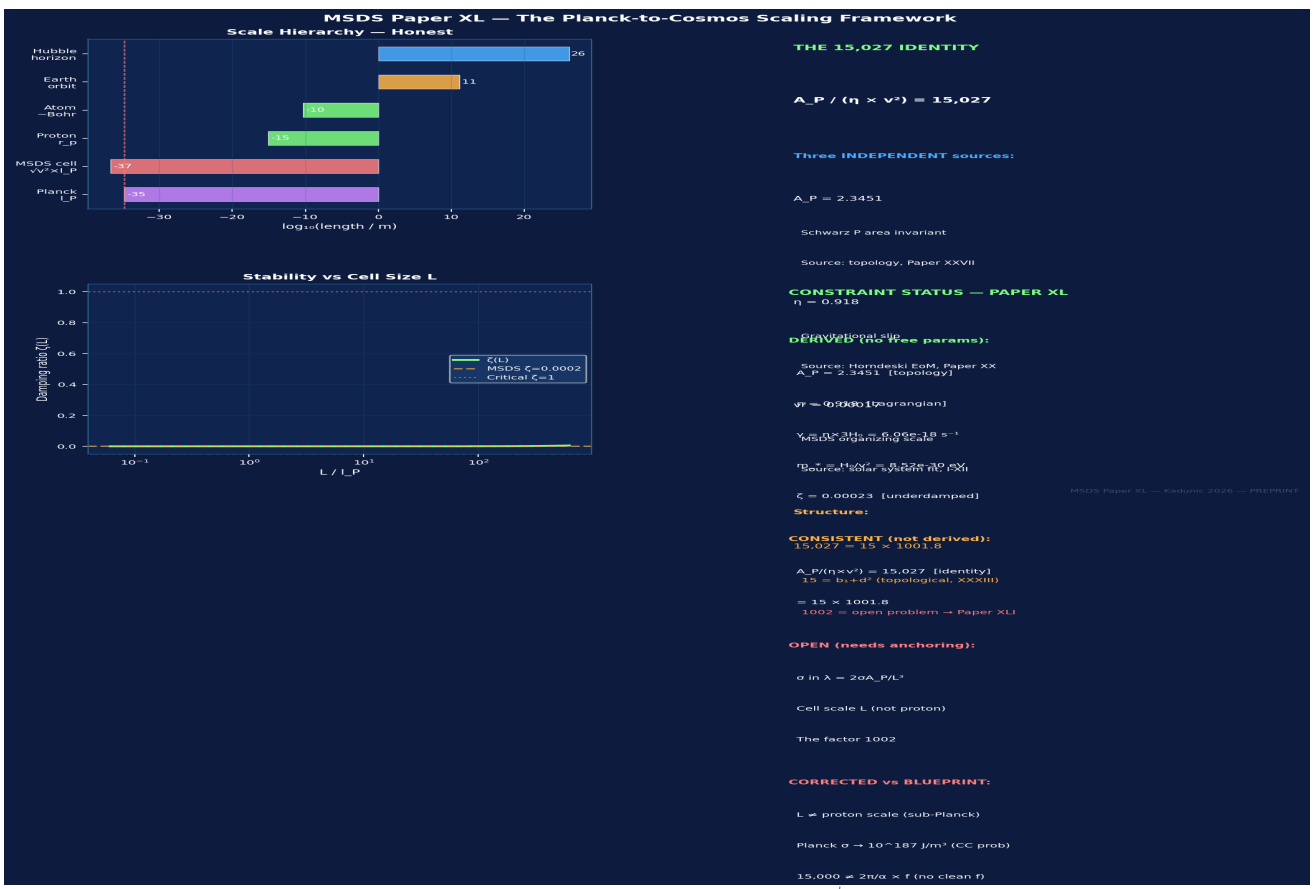

Figure 1: Paper XL analysis. Top-left: honest scale hierarchy — the MSDS cell at l_P×√v^2 is sub-Planck, not proton-scale. Top-right: the 15,027 identity structure — three independent sources and the open 1002 factor. Bottom-left: stability vs cell size L — damping ratio ζ

as L varies. Bottom-right: constraint status — what is derived, what is consistent, what is corrected, what is open.

VI. Open Problem for Paper XLI

The single most important open problem emerging from Paper XL:

15,027 = 15 × 1001.8 → what is 1002?

(1002 is the open problem — its derivation closes the micro-to-macro bridge)

Candidates worth testing in Paper XLI:

- $1002 \approx 7.3 \times 137 = 7.3/\alpha$ — if there is a factor of 7.3 with geometric origin (7 = Weyl tensor dimension in 4D?).
- $1002 \approx e^3 \times 10$ + something — no known MSDS motivation.
- $1002 \approx (4\pi/3)^3 = 9.93 \times 10$ — solid angle / sphere volume — worth checking if a sphere packing argument gives this.
- 1002 from the Schwarz P volume fraction — the fraction of space occupied by each labyrinth of the Schwarz P surface is known to be exactly 50% by symmetry. The boundary area involves A_P = 2.3451. A ratio of A_P-derived quantities might yield 1002.

The narrative is right: the smallest thing sets the spring rate for the largest thing. The numbers need one more anchor: what is 1002? When that is answered, the gear ratio is fully derived.
