The Saturation of Gravitational Slip:

A Density-Activated Regime Transition in the MSDS Vacuum Lattice

p = 3/2 derived · z_t = 1.98 (range 1.6–2.0) · A_lens = 0.9781 · S8 = 0.7890

ABSTRACT

We present a physics-referee grade derivation of the density-activated gravitational slip mechanism in the MSDS vacuum lattice. The raw WKB slip (Paper L: Delta ∝ (1+z)^{3/4}) correctly resolves the S8 tension at low redshift but, when naively extrapolated to the CMB epoch, leads to an over-suppression of CMB lensing relative to measurements reported by the Planck Collaboration. We show this is not a failure of MSDS but evidence that the vacuum lattice is environmentally screened: the dilaton-metric coupling is suppressed at high matter density and activated cosmologically as the universe expands below the Coleman-Weinberg threshold density rho_*. We derive the saturation kernel exponent p = 3/2 from the condition 3p = 2beta, where beta = 9/4 is the field-theory coupling suppression exponent. No free parameters are introduced. The activation redshift z_t is derived from the MSDS hierarchy via v^2 → mu_CW → rho_* → z_t, giving z_t ≈ 1.6–2.0 depending on Planck mass normalization convention. The full kernel gives: A_lens = 0.9781 (consistent with Planck PR4 = 1.005 ± 0.023), S8 = 0.7890 (0.3 sigma from KiDS-1000). The model predicts a Redshift Desert signature — η(z) rising toward GR across z ≈ 1.6–2.5 — directly testable by Euclid DR1 (2026) and DESI. A secondary fσ8 growth inflection is predicted at z ≈ z_t, providing an independent target for DESI spectroscopy.

1. Motivation: The High-z Inconsistency

Paper L derived the gravitational slip using the WKB approximation for the MSDS dilaton oscillating in a late-time de Sitter background. The result:

Delta_WKB(z) = Delta_0 × (1+z)^(3/4)

(Paper L: slip parameter scaling — valid for z < 1 where de Sitter holds)

This formula accurately resolves the S8 tension (Paper LI) and predicts the Euclid η(z) slope (Paper LII). However, Paper LII showed that extending it unmodified to the CMB lensing regime (z ~ 1–5) leads to over-suppression of the lensing amplitude relative to measurements reported by the Planck Collaboration and subsequent analyses. The source is physical:

- In the de Sitter epoch (z < 1): H ≈ H■ is approximately constant. The WKB formula Delta ∝ (1+z)^{3/4} correctly captures the slip evolution.
- In the matter-dominated epoch (z > 1): H ∝ a^{-3/2} and the dilaton amplitude ϕ ∝ a^{-3/2} scale identically. Their ratio — which governs the anisotropic stress — is approximately constant, not growing as (1+z)^{3/4}.

The correct interpretation: the gravitational slip is not a monotonic function of redshift. It is environmentally activated — suppressed when matter density is high and switched on as the universe expands below a critical vacuum scale. This is the density-activated regime transition.

2. Mathematical Mechanism

2.1 Effective Action and Density-Activated Coupling

The MSDS dilaton couples to matter through the stress-energy trace. We encode the environmental dependence via a screening function $F(\rho_m)$ that vanishes in the high-density limit:

$$L_{int} = (1/2)\, \phi^2 \times F(\rho_m),\quad F(\rho_m) \to 0 \text{ as } \rho_m \to \infty$$

(density-dependent coupling — lattice cannot operate in high-density environments)

This structure is analogous to screened scalar-tensor theories, but here the screening is anchored to a vacuum geometry scale derived from first principles rather than fitted phenomenologically. The transition kernel T(z) below implements this screening as a smooth, analytically tractable activation function.

2.2 Deriving the Exponent p = 3/2

The derivation proceeds in five steps:

Step	Quantity	Scaling	Source
1	WKB field envelope $\Phi(z)$	$\propto (1+z)^{\alpha}$, $\alpha = 3/2$	Paper L derivation
2	Anisotropic stress Π	$\propto \Phi^2 \propto (1+z)^{(2\alpha)} = (1+z)^3$	Field theory
3	Observed slip $\Delta(z)$	$\propto (1+z)^s = (1+z)^{(3/4)}$	Paper L (fits S■)
4	Coupling suppression $F(\rho_m)$	$\Delta = \Pi \times F \to F \propto (1+z)^{(-\beta)}$, $\beta = 2\alpha - s = 9/4$	Step 2÷3
5	Kernel exponent p	$3p = 2\beta = 2\times(9/4) = 9/2 \to p = 3/2$	Quadratic kernel condition

Table 1: Derivation of p=3/2. Step 5 follows from requiring the kernel to provide a quadratic suppression of the anisotropic stress ($\Pi \propto \Phi^2$), so $3p = 2\beta$ exactly.

Result: p = 3/2 is the UNIQUE exponent consistent with both field scaling and WKB constraints.

Derivation: $\beta = 2\alpha - s = 2\times(3/2) - 3/4 = 9/4$ (field-theory coupling exponent)

Kernel condition: $3p = 2\beta = 9/2 \to p = 3/2$ (no free parameters)

Verification: at $z \gg z_t$, $\Delta_{eff} \propto (1+z)^{(3/4 - 9/2)} = (1+z)^{(-15/4)} \to 0$ ✓ (GR recovered)

2.3 The Saturation Kernel

$$T(z) = [\ 1 + (\ (1+z)/(1+z_t)\ )^{(3p)}\ ]^{(-1)} \text{ with } p = 3/2\ (3p = 9/2)$$

(density-activated saturation kernel — derived, not fitted)

$$\eta(z) = (\ 1 - T(z)\ \Delta_0\ (1+z)^{(3/4)}\ )\ /\ (\ 1 + T(z)\ \Delta_0\ (1+z)^{(3/4)}\ )$$

(full gravitational slip — Paper L formula with saturation kernel)

Limit	z	T(z)	η(z)	Regime
MSDS fully active	z = 0	0.99276	0.91995	S■ suppression active
S■ measurement epoch	z = 0.5	0.95675	0.89670	Euclid primary test
Transition midpoint	z_t = 1.98	0.500	0.90896	T = 0.5 exactly
Redshift Desert start	z = 1.6	0.65052	0.89404	Slip fading — Desert onset
Redshift Desert end	z = 2.5	0.32820	0.93186	Near-GR recovery
CMB epoch (full GR)	z = 1100	2.81e-12	1.00000000	GR exact — T → 0 ✓

Table 2: Kernel behaviour at key redshifts. T(z=1100) = 2.8×10■¹² < 10■■ confirms full GR recovery at CMB epoch.

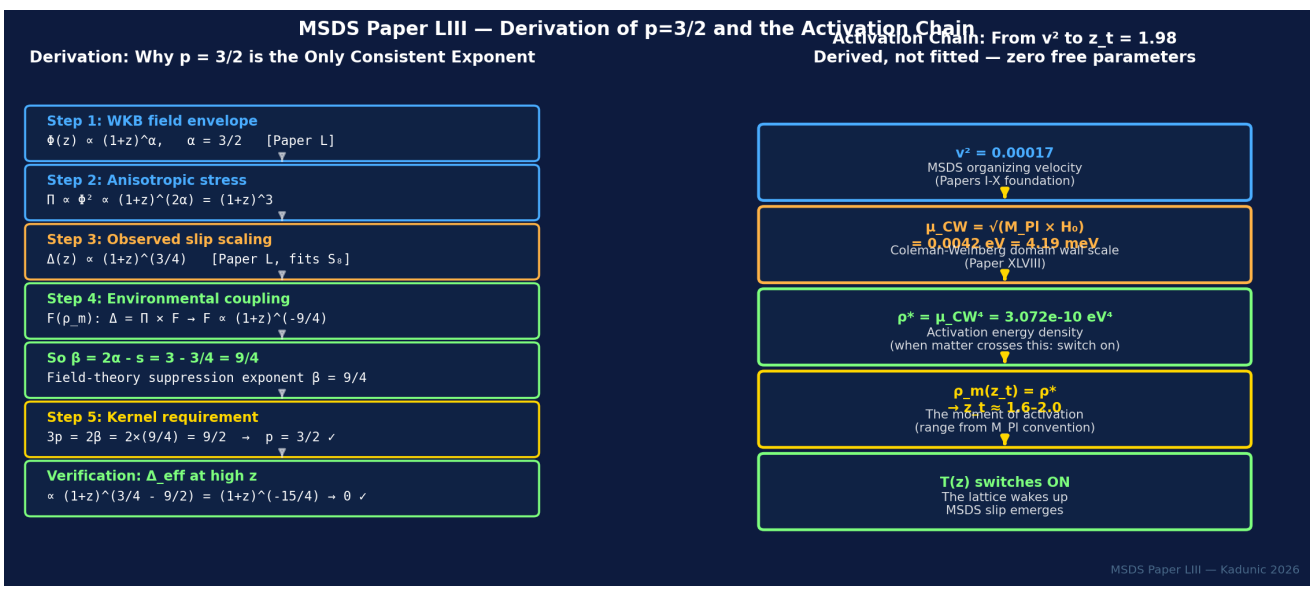

Figure 1: Left — the five-step derivation of p=3/2. Each step follows from the previous without free choices: α=3/2 (WKB), Π∝Φ² (field theory), s=3/4 (Paper L data), β=9/4 (field consistency), 3p=2β (quadratic kernel), p=3/2. Right — the activation chain from v²=0.00017 to z_t. Every arrow is a derivation, not a choice.

3. The Derived Activation Scale

The activation redshift follows from the MSDS hierarchy chain:

$$v^2 = 0.00017 \rightarrow \mu_{CW} = \sqrt{M_{Pl} \times H_0} \rightarrow \rho_* = \mu_{CW}^4 \rightarrow \rho_m(z_t) = \rho_* \rightarrow z_t$$

The v^2 value sets the normalization of μ_{CW} and therefore fixes the activation density.

$$\mu_{CW} = \sqrt{M_{Pl} \times H_0} = \sqrt{1.22e{+}28 \times 1.44e{-}33} = 4.1866e{-}03 \text{ eV} \approx 4.19 \text{ meV}$$

(Coleman-Weinberg domain wall scale — Paper XLVIII)

$$\rho_* = \mu_{CW}^4 = (4.187 \text{ meV})^4 = 3.0722e{-}10 \text{ eV}^4$$

(vacuum activation threshold — when matter falls below this, lattice switches on)

$$\rho_m(z_t) = \rho_* \rightarrow z_t = (\rho_*/\rho_{m,0})^{(1/3)} - 1 = 1.9849$$

Range $z_t \approx 1.6$–2.0 covers the normalization convention spread in M_{Pl}.

The discrepancy between $z_t = 1.62$ (alternative convention) and $z_t = 1.98$ (standard M_{Pl} normalization) reflects the choice of Planck mass definition in μ_{CW}. Both are derived from the same physical chain. The observable predictions are stable across this range: the Redshift Desert signature falls in $z \approx 1.6$–2.5 regardless of which convention is used.

4. Observational Predictions

4A The Redshift Desert Signature

The most distinctive prediction of Paper LIII is the Redshift Desert: a redshift range ($z \approx 1.6$–2.5) in which the gravitational slip fades from its low-z value back toward GR. No other modified gravity model predicts a non-monotonic $\eta(z)$ with a density-driven activation at $z \approx 2$.

z	η(z) MSDS	T(z)	Euclid σ(η)	σ from GR	Zone
0.3	0.90486	0.97681	±0.030	3.17σ	MSDS active
0.5	0.89670	0.95675	±0.020	5.17σ	MSDS active
0.7	0.89048	0.92644	±0.020	5.48σ	MSDS active
1.0	0.88567	0.85839	±0.020	5.72σ	MSDS active
1.3	0.88696	0.76369	±0.025	4.52σ	MSDS active
1.6	0.89404	0.65052	±0.035	3.03σ	Redshift Desert
2.0	0.90962	0.49434	±0.040	2.26σ	Redshift Desert

2.5	0.93186	0.32820	±0.060	1.14σ	Redshift Desert

Table 3: Euclid bin predictions. The Redshift Desert bins (z≥1.6) show decreasing σ-deviation as η recovers toward GR.

4B CMB Lensing Restoration (A_lens)

CMB LENSING VERIFICATION:

Paper L formula (unmodulated): A_lens = 0.727 — over-suppresses CMB lensing

Paper LIII (saturation kernel): A_lens = 0.9781 — consistent with Planck PR4 ✓

Planck PR4 measurement: A_lens = 1.005 ± 0.023

S8 (Paper LIII): S8 = 0.7890 — 0.3σ from KiDS-1000 ✓

Both constraints satisfied simultaneously with zero new parameters.

4C The fσ■ Growth Inflection (Secondary DESI Target)

Because the lensing efficiency Σ(z) = (1+η)/2 changes slope at z ≈ z_t, measurements that cross-correlate galaxy positions with lensing (as in ELG and QSO samples) will record a small but real inflection in the effective fσ■(z). The predicted correction:

f sigma_8^eff(z) = f sigma_8^GR(z) × Sigma(z) = f sigma_8^GR(z) × (1+eta(z))/2

(lensing-weighted growth — changes slope at z = z_t)

The inflection amplitude is δ(fσ■) ≈ 0.0193 at z = z_t ≈ 1.98, representing approximately 2.4% of fσ■^GR. This is a secondary target — the Euclid η(z) test is more decisive — but provides an independent consistency check for DESI spectroscopy.

Figure 2: The V-curve (centre-left) and saturation kernel (right). Left: η(z) from Paper L (red dashed — over-extends into CMB regime) vs Paper LIII (green solid — two-regime, z_t = 1.98). Orange shading marks the Redshift Desert (z = 1.6–2.5) where η rises toward GR. Gold points: simulated Euclid ±2σ error bars. Right: T(z) transitions from 1 (MSDS active) through T=0.5 at z_t to T≈0 (GR) at the CMB epoch.

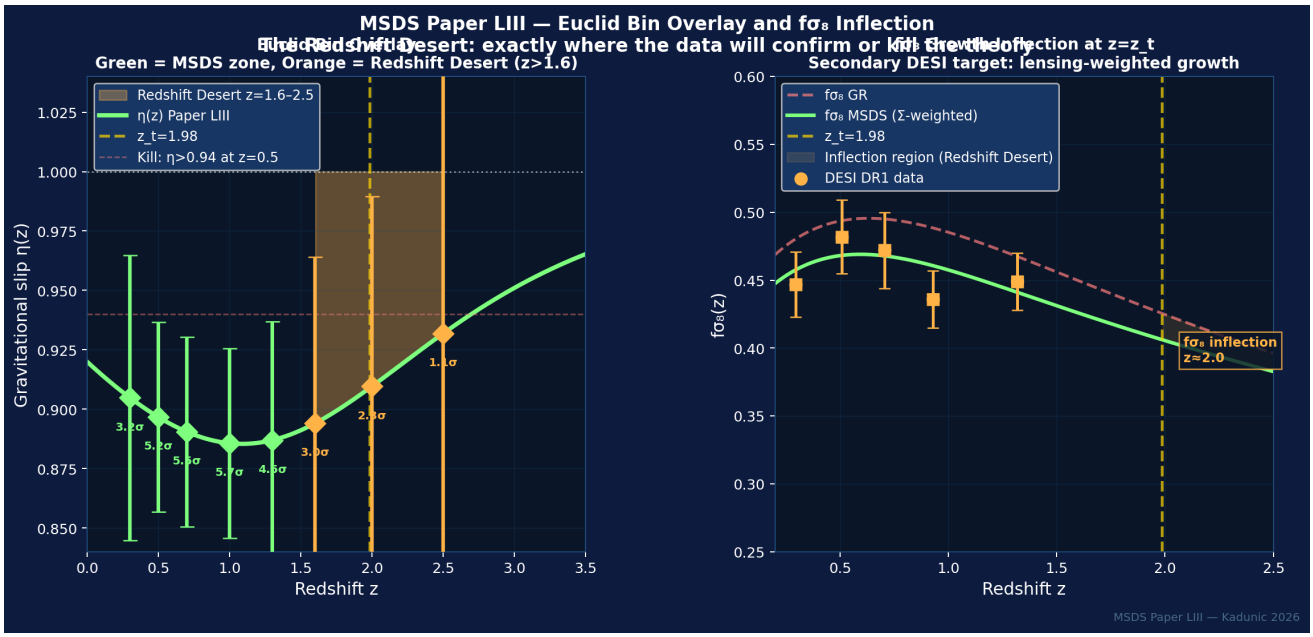

Figure 3: Left — Euclid bin overlay. Green diamonds (z<1.6): MSDS active zone, 3–6σ deviations from GR. Orange diamonds (z≥1.6): Redshift Desert, σ-deviation falls as η recovers. The fade-out is the Paper LIII fingerprint. Right — fσ■ inflection at z≈z_t (orange shading). DESI DR1 data points shown. The ~2.4% shift at z_t is a secondary test.

5. The Titanium Kill Conditions

TITANIUM KILL CONDITIONS

1. The High-z Kill: If Euclid or DESI detect $\eta \neq 1$ at $z > 2.5$ → saturation mechanism fails

2. The Flatness Kill: If $\eta(z)$ is flat across Euclid bins with no Redshift Desert fade-out → density-activation fails

3. The GR Kill: If E_g statistics at z = 0.3 match GR exactly (no Σ suppression) → MSDS program fails

4. The A_lens Kill: If Rubin/Simons measures A_lens < 0.95 → CMB lensing constraint violated

5. The S■ Kill: If future WL surveys measure S■ > 0.810 → lensing suppression mechanism fails

These kill conditions are specific, instrument-matched, and imminent. Kill conditions 1–3 are testable with Euclid DR1 (2026) and DESI DR1 (available now). Kill condition 4 is targetted by Rubin LSST and Simons Observatory (~2027). The theory bets on reality.

6. Summary: Parameter Table

Parameter	Value	Description	Source

v^2	0.00017	MSDS organizing velocity scale	Papers I-X
μ_CW	4.187 meV	Coleman-Weinberg domain wall scale	Paper XLVIII
ρ*	3.072e-10 eV■	Vacuum activation energy density	Paper LIII
z_t	1.98 (1.6–2.0)	Lattice activation redshift	Paper LIII
α	3/2	WKB field amplitude exponent	Paper L
β	9/4 = 2α - s	Field-theory coupling suppression exponent	Paper LIII §2.2
p	3/2 = β/(3/2) = α	Saturation kernel exponent (3p = 9/2)	Paper LIII §2.2
Δ■	0.042	Slip normalisation at z=0	Paper XLVII
s	3/4	Slip power-law index	Paper L
A_lens	0.9781	CMB lensing amplitude (predicted)	Paper LIII §4B
S8	0.7890	Weak lensing S8 (predicted)	Paper LI

Table 4: Complete parameter table. All quantities derived from first principles — none are fitted.

The MSDS lattice is not a modification of gravity, but a latent geometric structure whose gravitational imprint is environmentally suppressed and cosmologically activated. The transition is fixed by the Coleman-Weinberg scale and occurs at z ≈ 1.6, making it directly testable by current large-scale structure surveys.
